ABSTRACT

The measurement of medical images can be hindered by blur and distortions caused by the physiological motion. Specially for retinal imaging, images are greatly affected by sharp movements of the eye. Stabilization methods have been developed and applied to state-of-the-art retinal imaging modalities; here we intend to adapt them for coherent light detection schemes. In this paper, we demonstrate experimentally cross-correlation-based lateral and axial motion compensation in laser Doppler imaging and optical coherence tomography by digital holography. Our methods improve lateral and axial image resolution in those innovative instruments and allow a better visualization during motion.

Index Terms— Motion Compensation, Cross-correlation, Digital Holography, Optical Coherence Tomography, Laser Doppler Holography.

1. INTRODUCTION

Optical interferograms are recorded with a laser Doppler instrument [3] in human eyes, and with a holographic OCT instrument in synthetic phantoms. For the laser Doppler setup, the source is a laser diode emitting at the wavelength $\lambda = 785$ nm. The camera records $2048 \times 2048$-pixel images corresponding to the $(x, y)$ plane, at a frame rate of $\omega_S/(2\pi) = 80$ Hz with 8 bit/pixel quantization. For OCT, the beam is emitted by a tunable laser and varies from $\omega_1$ to $\omega_2$, which are linked to the wavelengths $\lambda_1 = 870$ nm and $\lambda_2 = 820$ nm by $\omega = 2\pi c/\lambda$, where $c$ is the speed of light, with a sweep time $T = 0.5s$. The camera records $1024 \times 1024$-pixel images at a frame rate of $\omega_S/(2\pi) = 512$ Hz with 16 bit/pixel quantization. Digitized interferograms from the camera are processed in real-time with the Holovibes\textsuperscript{1} software to compute and visualize holograms, and saved for offline processing.

2. HOLOGRAPHIC IMAGING

2.1. Setup

Optical interferograms are recorded with a laser Doppler instrument [3] in human eyes, and with a holographic OCT instrument in synthetic phantoms. For the laser Doppler setup, the source is a laser diode emitting at the wavelength $\lambda = 785$ nm. The camera records $2048 \times 2048$-pixel images corresponding to the $(x, y)$ plane, at a frame rate of $\omega_S/(2\pi) = 80$ Hz with 8 bit/pixel quantization. For OCT, the beam is emitted by a tunable laser and varies from $\omega_1$ to $\omega_2$, which are linked to the wavelengths $\lambda_1 = 870$ nm and $\lambda_2 = 820$ nm by $\omega = 2\pi c/\lambda$, where $c$ is the speed of light, with a sweep time $T = 0.5s$. The camera records $1024 \times 1024$-pixel images at a frame rate of $\omega_S/(2\pi) = 512$ Hz with 16 bit/pixel quantization. Digitized interferograms from the camera are processed in real-time with the Holovibes\textsuperscript{1} software to compute and visualize holograms, and saved for offline processing.

2.2. Acquisition of interferograms

A Mach-Zehnder interferometer has been used to record interferograms. It consists in making interfere two beams from the same laser source. The source is split between reference and object arms. The light wave from the object arm is backscattered once the sample is reached and interferes in the camera

\textsuperscript{1}http://holovibes.com
2.3. Processing of optically-acquired interferograms

Interferogram rescaling with wavelength. In order to avoid the distortion of the signal, the impact of the sweep in OCT needs to be considered to propagate the interferograms \( I \) from the camera plane to the retina or image plane. In fact the size of the pixels in the image plane depends on the wavelength of the beam and of the distance between camera and image planes \([12, 13]\): \( d' = \lambda z/(Nd) \), where \( d \) and \( d' \) are the lateral size of a pixel from camera plane and from image plane, respectively. \( z \) is the distance between both planes and \( N \) is the number of pixels in one lateral dimension. Because of the sweep of the source, the pixels of the image plane shrink with wavelength (arrow (1) of Fig. 1). To circumvent lateral field variation with wavelength, each interferogram is resampled by linear interpolation of the calculation grid with a different pitch (arrow (2) of Fig. 1). The rescaled interferogram is:

\[
I'(x, y, t) = I(x\lambda/\lambda_1, y\lambda/\lambda_1, t),
\]

where \( \lambda \) is the current wavelength. In the case of laser Doppler imaging, the optical wavelength \( \lambda \) is kept constant, hence the interferogram does not need to be rescaled: \( I' \equiv I \).

Spatial demodulation by Fresnel transform. The propagation of the fields from camera to image plane is carried out by a Fresnel transform [11] (arrow (3) of Fig. 1), which gives the hologram \( H(x, y, t) \):

\[
H(x, y, t) = \frac{i}{\lambda z} \exp(-ikz) \iint I'(x', y', t) \exp \left[-\frac{i\pi}{\lambda z} \left((x - x')^2 + (y - y')^2\right)\right] dx' dy'.
\]

The argument of the complex-valued hologram in the cross-contribution region is the phase difference \( \phi \) between the optical fields \( E \) and \( E_{LO} \) in the image plane.

Temporal demodulation by Fourier transform. In swept-source OCT, the instantaneous beating frequency \( \partial\phi/\partial t = \omega \) scales up linearly with axial depth \( z \) [5], whereas in laser Doppler, it describes local velocities of the scatterers [7]. Hence for both methods, temporal signal demodulation is performed by short-time Fourier transform (STFT) (arrow (4) of Fig. 1). Time-and-space-dependent spectrograms \( \tilde{H}(x, y, t, \omega) \) are calculated from the stream of intermediate holograms \( H(x, y, t) \):

\[
\tilde{H}(x, y, t, \omega) = \int H(x, y, \tau) g_T(t - \tau) e^{-i\omega\tau} d\tau,
\]

where \( g_T(t) \) is a time gate of width \( T \) at time \( t \). Then, the envelope \( |\tilde{H}| \) of the STFT of \( H \) is formed (arrow (5) of Fig. 1). The quantities \( |\tilde{H}(x, y, t, \omega)| \) are the images in laser Doppler and OCT on which motion compensation will be performed.

3. MOTION COMPENSATION METHODS

3.1. Lateral Motion Compensation

We form Doppler-contrast images at the Nyquist frequency \( \omega_S/2 \) by calculating Eq. (4) with a time gate \( g_T \) of two points (\( T = 25 \text{ ms} \)). To compensate lateral motion (in \( x, y \) plane), we use a cross-correlation-based stabilization algorithm. The human eye is constantly subject to deviations, saccades and tremors. Added to heartbeat and respiration motion, those movements can shift or even remove the object of interest from the image during several frames. Thus, a processing chain has been built in order to keep important structures in the center of the en-face image.

A reference image \( f_1 \) is made by averaging \( n = 10 \) consecutive images, and compared to a moving average \( f_2 \) of
Fig. 2: Retinal image stabilization by lateral \((x, y)\) motion compensation of intensity holograms (Section 3.1). The white scale bars indicate 200 \(\mu\)m.

\[
\begin{align*}

\[
\begin{align*}
\text{a) Before processing} & \quad \text{b) After rescaling (Eq. (2))} \\
\text{c) Before processing} & \quad \text{d) Likewise (b)}
\end{align*}
\]

\[
\begin{align*}
\text{3.2. Axial Motion Compensation} & \\
\text{We form OCT images by calculating Eq. (4) with a time gate} & \quad g_T \text{ of 256 points (} T = 0.5 \text{ s). Axial motion during the recording process has a negative impact on the reconstruction of OCT images: when an axial drift occurs, the depth information encoded in the beating frequency of the interferogram is inaccurate, adding an offset phase to the signal and decreasing in-depth accuracy. The principle of the compensation method is to identify where the phase shift due to the axial motion occurs by using STFT [15] on 20-point windows. Indeed, a global axial displacement of the sample during acquisition can be spotted in the time Fourier domain, where it corresponds to a frequency shift.}
\end{align*}
\]

\[
\begin{align*}
\text{For } y = y_0, \text{ the reference image } f_1 \text{ and the sliding image } f_2 \text{ are defined as the modulus of the STFT of } H(x, y_0, t) \text{ whose sub-windows are fixed or moving, respectively:} \\
& = \left| \sum_{\tau=1}^{n} e^{i\omega_{S}t_{\tau}/2} \right| / n, \\
& = \left| \sum_{\tau=1}^{n} e^{i\omega_{S}(t + \tau)} \right| / n. \\
\end{align*}
\]

\[
\begin{align*}
\text{The quantitative comparison is performed with a normalized and centered cross-correlation [14]. The difference between the position of the maximum value and the center of the correlation matrix } \gamma \text{ gives the displacement between the two images. Resulting shifts describe retina lateral motion.}
\end{align*}
\]

4. RESULTS

Fig. 2 shows retinal vessels acquired by laser Doppler imaging. Fig. 2a is the whole 2048 \(\times\) 2048 image. The cross-beating interferometric contribution, which is the object of interest in the right bottom side of the image, is spatially separable from the other parts because of the off-axis configuration. Fig. 2b shows the focus on retinal vessels. Vega...
sels are moving in the image and sometimes disappear during several frames. Then, vessels do not appear clearly on the time-averaged image of 324 consecutive frames (Fig. 2c). After lateral stabilization, vessels are more visible on the time-averaged image: motion compensation is efficient. Although motion compensation is less efficient when the image changes too often, it improves overall image quality.

Fig. 3 and Fig. 4 are swept-source OCT images of samples composed of 1.5 mm diameter glass beads rolled in a single tape layer. Fig. 3 shows the in-depth profile \((x, \omega)\) of this sample corresponding to the y-axis represented by dotted lines in Fig. 4. Fig. 4 shows the en-face \((x, y)\) images at two different depths corresponding to the dotted lines in Fig. 4. Fig. 4a and 4b correspond to the red dotted line (depth of 1.1 mm) in Fig. 3, and Fig. 4c and 4d correspond to the green dotted line (depth of 1.5 mm) in Fig. 3. In Fig. 4a and 4b, the target layer is located between tape and beads: the beads on the left are at the same elevation as the tape layer on the right which starts to be sectioned.

A difference of lateral resolution is visible on images of Fig. 4. The interferogram rescaling allows the contours of the beads to be cleaner. Comparing Fig. 3a and Fig. 3b shows an improvement in axial resolution, which is also noticeable on en-face images: in Fig. 4c, beads on the right seem almost at the same elevation than beads on the left, because the depth accuracy is low, while in Fig. 4d, right beads clearly belong to a different layer. Axial motion correction can be seen in Fig. 3c: the accuracy is improving and the different layers are better separated. Besides, the optical bench will be strengthened to reduce mechanical noise, in order to further improve the axial accuracy of depth images.

5. CONCLUSION AND PROSPECTS

We have demonstrated lateral and axial motion compensation in laser Doppler holography and holographic OCT by cross-correlation stabilization, respectively. This method is suited to our images and cancels efficiently the effects of motion. Besides, the reported results are non-iterative and compatible with real-time processing at high throughput on graphics processing units. A real-time implementation of lateral motion compensation has been implemented.\(^2\) The reported results in motion compensation pave the way towards the design of high resolution computational imaging for the retina in real-time by digital holography.

Aside from motion, retinal imaging suffers from phase distortions caused by the eye: the light backscattered by the retina crosses lenses in the eye, which can cause aberrations. As a future work, we will try to correct optical aberrations.
